INTRODUCTION

To get a good estimate of the thickness distribution of drift ice at a given location it is necessary with relatively frequent observations from in situ instruments. Moored upward looking sonars (ULS) seem in this respect to represent an interesting tool.

The first deployments were made in the Fram Strait in 1986 and in the Barents Sea in 1987, both unsuccessfull due to battery failures. In addition two other instruments deployed in the Barents Sea were lost, probably due to trawling activities. This miserable start was, however, somewhat compensated by a successfull retrieval of the first one year long recording from the Greenland Sea in June 1988, which will be reported on below.

INSTRUMENT

The upward looking sonar (ES-300-II) was manufactured by Chr Michelsens Institute (CMI), Bergen. The instrument specification and mooring configuration are given in Table 1 and on the front page.

Table 1

Technical specifications of CMI ES-300-II.

Operational depth.....	20-70 m
Sonar beam width.....	5.0 deg
Operational acoustic frequency.....	300 kHz
Resolution.....	~0.1 m
Pressure transducer range.....	20-70 m
Resolution.....	0.02 m
Tilt (XY) resolution.....	1 deg
Data recording interval.....	4 min
Data recorder.....	Sea Data Model 610
Storing capacity (300 ft cassette).....	~550 days
Total length of instrument.....	1.70 m
Diameter of float.....	0.55 m
Diameter of cylinder.....	0.16 m
Weight in air, without float.....	58 kg
Total weight in air w./float.....	79 kg
Net buoyancy in sea water.....	~55 kg

RECORDING SPECIFICATIONS

Sonic transit time.

The distance from the sonar head to the underside of the ice is based on four sonar shots of which the two most equal transit times are stored. As one series of observation is performed every 4 minutes this corresponds to about 130 000 pairs of ice draft observations per year. The average of the two stored transit times (S_1 and S_2) is used as basis for the calculation of the ice draft. The mean one-way transit time S (s) is given by the formula:

$$1) \quad S = ((1/4)(S_1 + S_2)(0.0000512) + 0.00004) \text{ s}$$

provided by the manufacturer.

Observations where the first stored transit time exceeds 0.05 s and where the difference between the two stored transit times exceeds 0.001 s have been deleted. A transit time difference of 0.001 s corresponds to a draft difference of about 1.4 m. In addition, we have deleted observations where the average transit time indicates reflection from objects more than 1 m above the water surface (here denoted as negative draft larger than 1 m). The latter filtering excludes abnormal recordings (possibly due to scattering of the return signal) but includes negative recordings which may be expected due to wave effects in the ice margin. With an ULS depth of 50 m the sonar beam, having an aperture of 5 degrees, will have a circular footprint with a diameter of 4-5 m and is thus capable of detecting the water surface in fairly narrow leads. This indicates that wave effects - not being detected by the pressure transducer - may be reflected in the sonar signal. It is seen that the majority of the negative drafts is generally less than 0.5 m (ANNEX A).

The ULS may during ice free conditions operate as a wave detector. See registrations from the periods 18-21 September 1987 and 15-20 February 1988 reproduced in ANNEX A.

The speed of sound in water is determined from the equation given by Kinsler and Frey in "Fundamentals of Acoustics". An error of one degree C in the water temperature yields a corresponding ice draft error of 0.33 m. As we have no registration of temperature in the actual water column we have applied a sound velocity of 1442 m s^{-1} corresponding to a water temperature of -1.0°C and a salinity of 33 per mille at the average depth of 25 m. A one per mille error in the salinity corresponds to an error in the ice draft of 0.12 m. (These parameters will be adjusted later when oceanographic recordings become available.)

A control of the accuracy of the calculated ice draft is provided by the registrations collected during conditions with open, calm water above the sonar during summer conditions. See recordings for the last and first part of June 1987 and 1988, respectively, in ANNEX A. These registrations suggest an average accuracy in the order of 10 cm.

Instrument depth variations.

The maximum variation of the instrument depth during the period (365 days) was close to 30 m. This variation is in all probability due to a

variable drag on the 1200 m long mooring line caused by changing current velocities. Smaller depth variations, probably caused by the tides, are clearly seen in the recordings (Fig. 1).

The range of the pressure transducer was exceeded on a number of occasions when the sonar was forced down to depths below 70 m. For practical reasons it is also difficult to determine the accurate level of operation in advance during deep sea deployments. To secure a continuous operation of the ULS it is therefore important to have a pressure transducer with a sufficiently wide range.

The pressure is given in numerical units varying between 0 and 4095 (0-70 m). Recordings above 4095 have been deleted. The pressure (P) is given in pascal by

$$2) \quad P = ((P_o) (195.494) - 4369.6) \text{ pa}$$

where P_o is the observed numerical unit. A Digiquartz 8060 D.S. has been used as reference for the calibration of the pressure transducer.

The tilt.

The tilt is recorded in degrees directly within the range of 0-45°. The vertical orientation of the instrument turned out to be very stable with deviations mainly below 3 degrees. This was to some extent unexpected, but indicates that the instruments buoyancy balance is influenced to a small extent by the inclination of the 1200 m long mooring line.

A tilt of e.g. 10 deg. corresponds to a correction of 0.8 m while the majority of the tilts, which are less than 3 deg., corresponds to a correction of 0.07m. The tilting effect is corrected for in the calculations of the draft (using the cosine). Observations indicating a tilt above 20° have been deleted.

DEPLOYMENT AND RETRIEVAL

The ULS was deployed at a nominal depth of 45 m. It was attached to the top of a current meter mooring of E. Fahrbach, Alfred-Wegener Institute for Polar and Marine Research (AWI). The instrument was deployed from R/V Polarstern at 75°03.4'N and 12°09.2W on 22 June 1987 at 0930 UT and retrieved from the same ship on 20 June 1988 at 1800 UT.

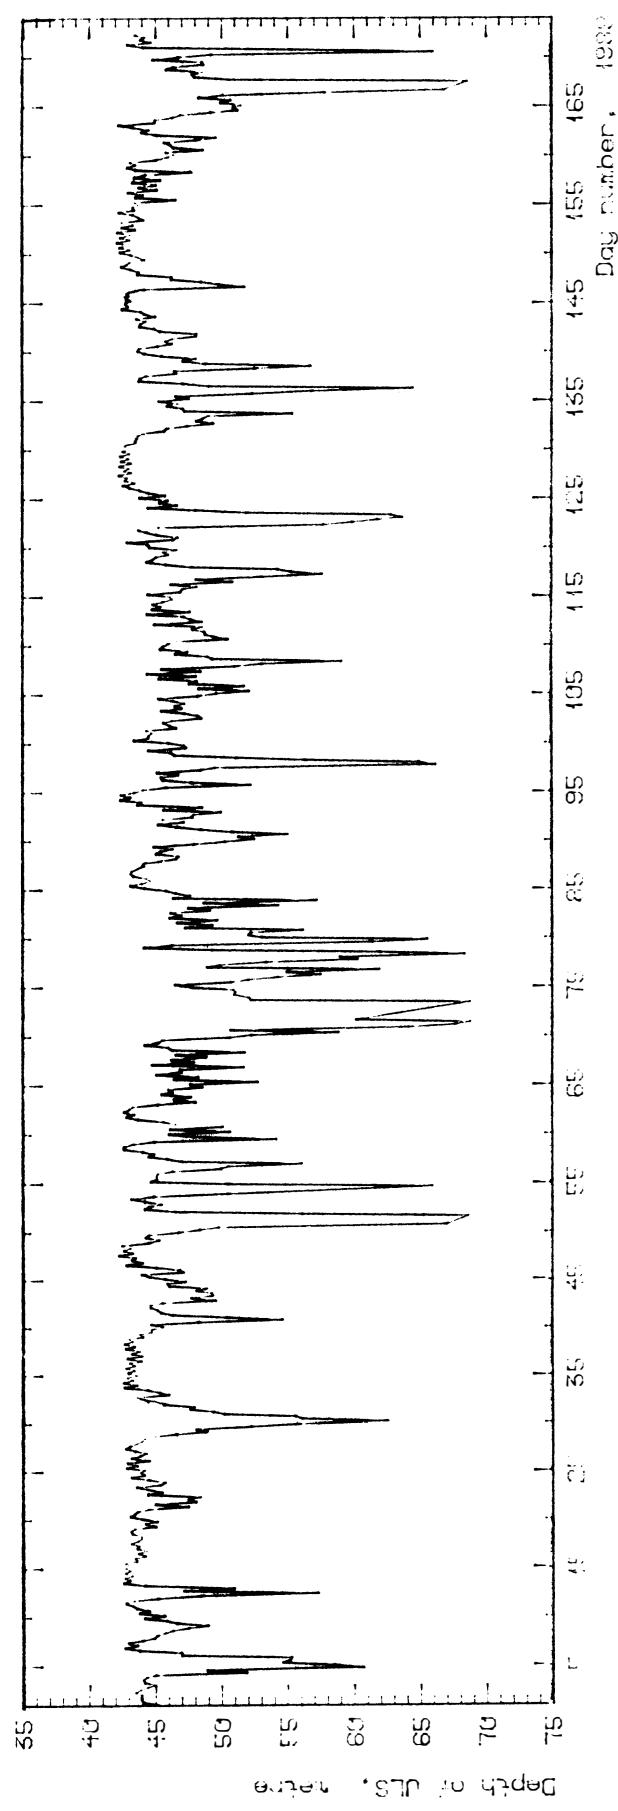

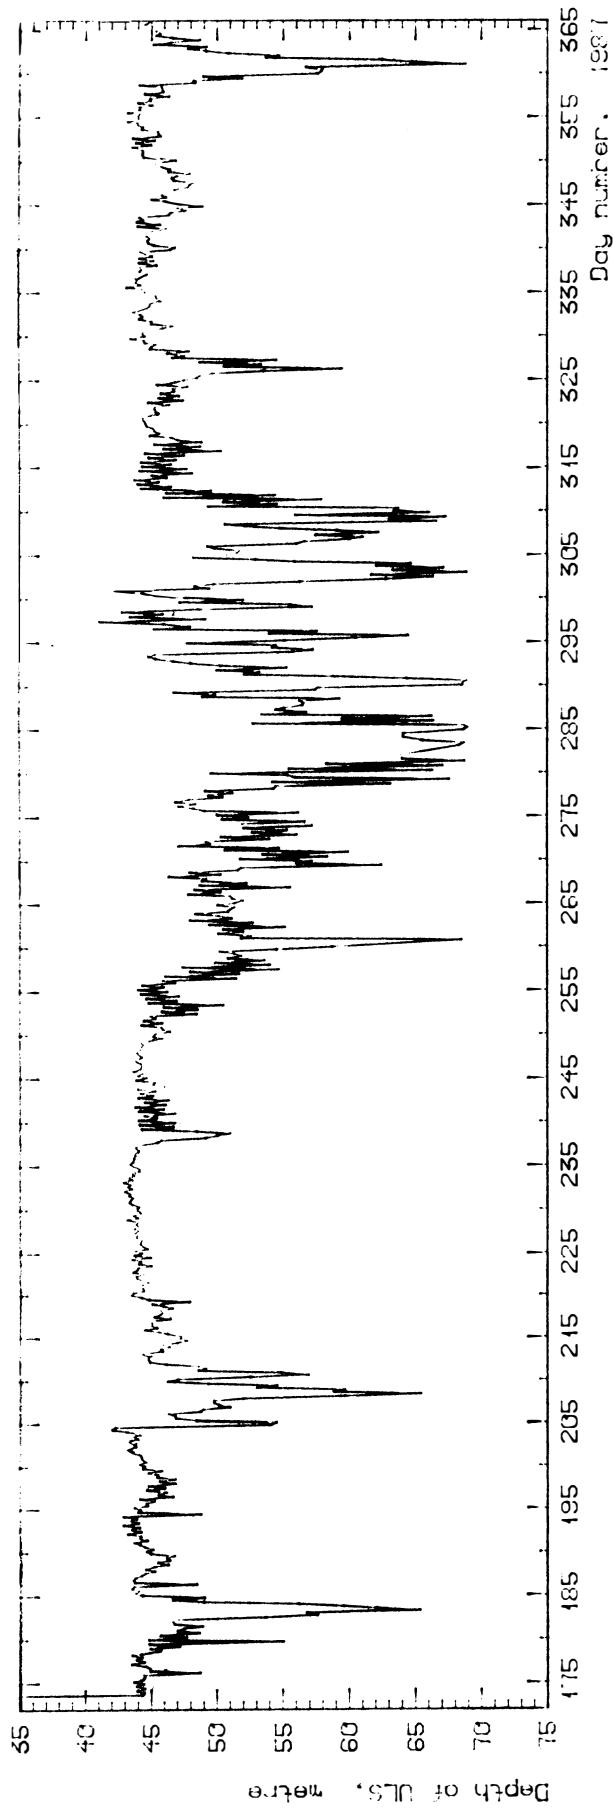

Fig. 1
Selection of 6 hours interval recordings of the depth of the ULS as observed by the pressure transducer.

ICE DRAFT DISTRIBUTIONS

The ice draft (D) was calculated from the relationship

$$3) \quad D = (D_p - D_s - 0.13) \text{ m}$$

where D_p is the depth calculated from the pressure, D_s is the distance from the sonar head to the underside of the ice as calculated from the sonar transit times, and 0.13 is the distance between the sonar head and the pressure transducer in the ULS housing. D_p is calculated from the formula

$$D_p = (P - A)/(\rho g)$$

where P is the recorded pressure estimated from Eq.2), A is the atmospheric pressure read from weather maps, ρ is the density of the water = 1026 kg m^{-3} for a 33 per mille salinity content, and g is the gravity constant 9.829 m s^{-2} . D_s is calculated from the formula

$$D_s = S V \cos(\tau)$$

where S is the mean one-way sonar transit time to the underside of the ice calculated from Eq. 1), V is the speed of sound ($=1442 \text{ m s}^{-1}$), and τ is the observed tilt.

Recordings (ANNEX A)

Lines have been drawn between the consecutive draft observations which are indicated by a bend in the continuous curve. This is clearly illustrated in the first two high resolution graphs in the annex. A broken line indicates that three or more consecutive readings have been rejected. The following graphs show the calculated draft observations for consecutive 15 day periods. The time resolution is here too small for an indication of all the single observations. The graphs reveal, however, the general impression of a fairly monotonous recording during the year, indicating a more or less continuous flow of ice with a highly variable draft. Some statistics and the number of rejected data are given in tables in ANNEX B.

The recordings indicate only a few periods with marked wave effects in the marginal ice zone, e.g., 18-21 September 1987 and 15-20 February 1988. An exceptionally thick ice feature seems to have passed the ULS site on 24-25 July 1987.

Tables (ANNEX B)

The tables give the frequency distribution of the various ice draft intervals observed together with some statistics. The restrictions for the filtering applied to the various sensor values result in some overlapping, the total number of rejected observations does therefore not always correspond with the sum of the individual rejections.

In addition to the filtering applied to the recordings (ANNEX A) we have here omitted negative drafts above 0.2 m. Draft observations between -0.2 and 0.0 m have also been given the value 0.0 m.

The 15 day mean ice drafts vary between 1.36 and 3.93 m with an annual average of 2.38 m. There is no systematic seasonal variation.

Note that the calculated average floe size and its standard deviation are given in minutes. It is defined as the period elapsed between two consecutive recordings of ice thicknesses less than 0.5 m. Applying the observed average drift velocity of $0.17 \text{ m s}^{-1} = 10 \text{ m min}^{-1}$ (Vinje and Finnekåsa 1986: Norsk Polarinstitutt Skrifter Nr 186), we estimate the average floe size to vary between 200 m and 3200 m, with the largest sizes during the colder season as should be expected.

VOLUME TRANSPORTS

Assuming the density of water and ice to be 1025 and 920 kg m^{-3} , respectively, we get an annual average ice thickness of $((1025/920) \times 2.38 =) 2.65 \text{ m}$, corresponding to about 70% of the average ice thickness of 4 m as observed in the Fram Strait. (See e.g. ref. above).

Assuming the width of the East Greenland Current to be 220 km at 75° N and applying the observed annual drift speed of 0.17 m s^{-1} , we obtain a preliminary annual ice volume transport past this latitude of about 3000 km^3 for the year-long period in question. This amounts to about 70% of the estimated average ice transport across the 80th parallel in the Fram Strait (see ref. above).

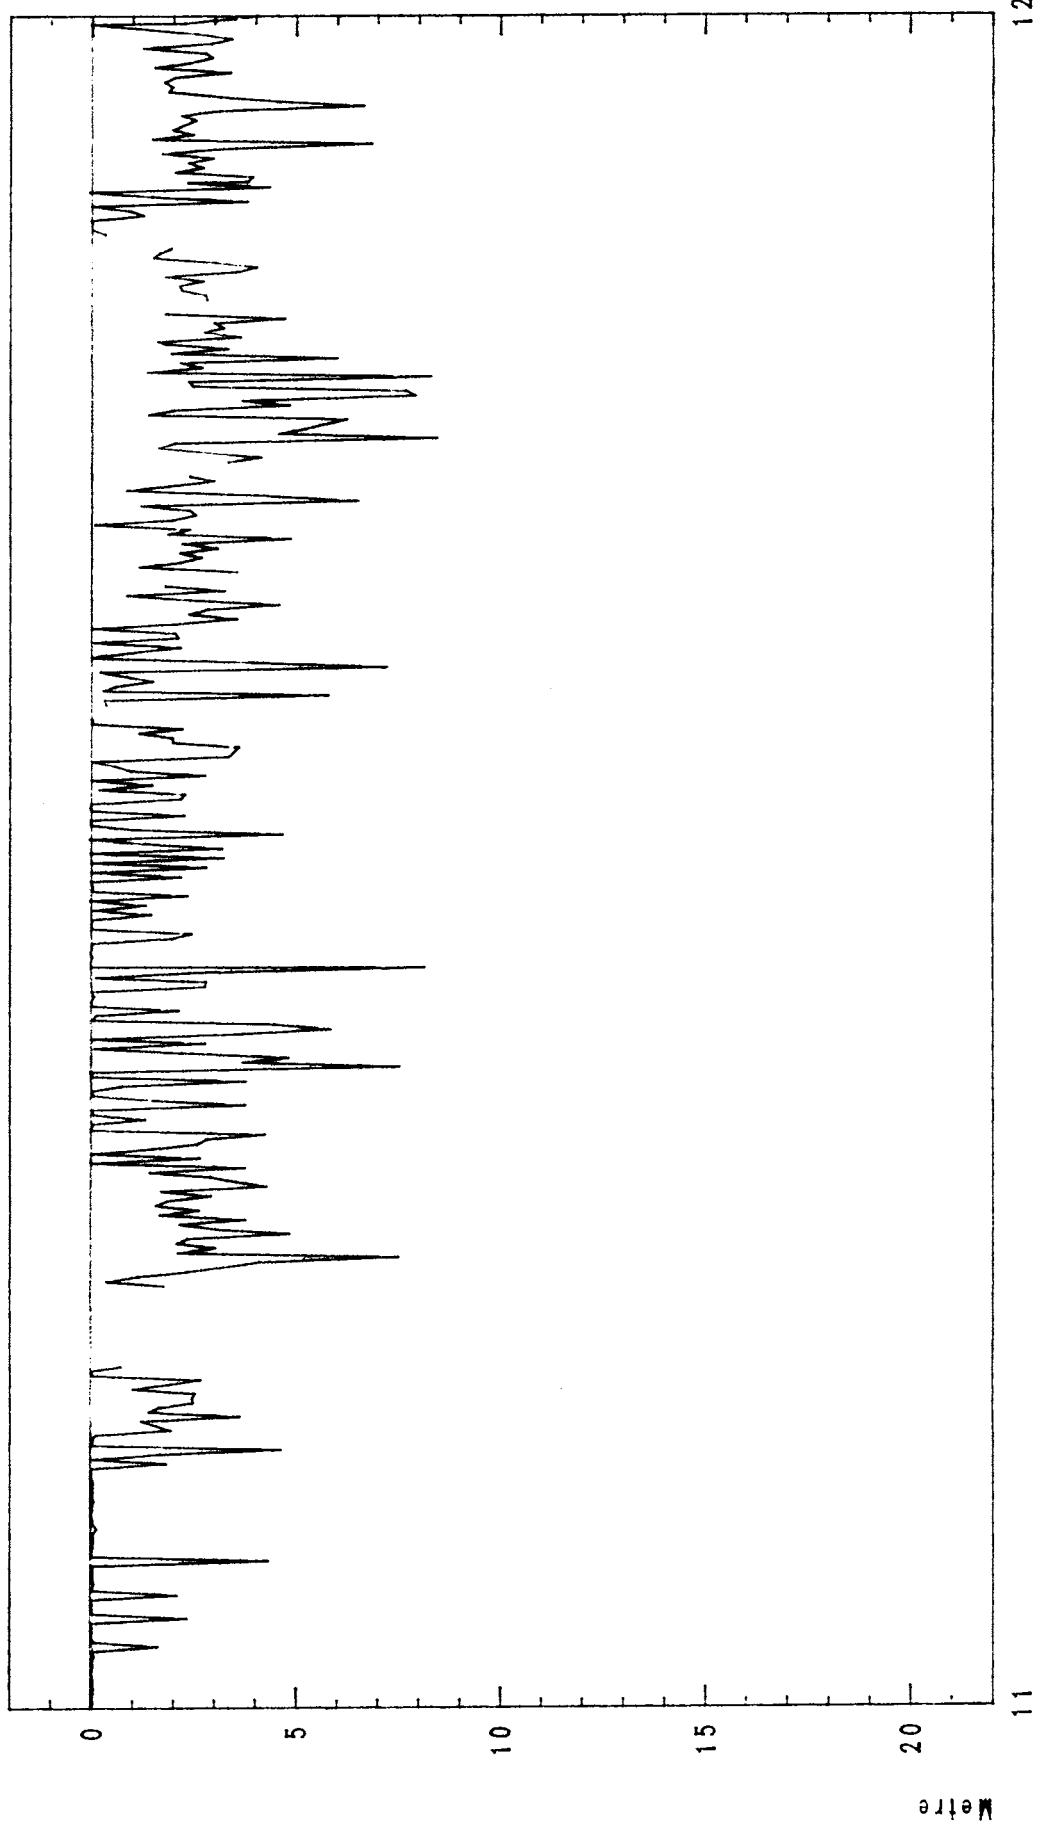

ACKNOWLEDGEMENTS

We are very grateful to the cruise leader Jens Meincke, University of Hamburg, and to Clark Darnell, NOAA, for their help during deployment and retrieval. Thanks are also extended to Eberhard Farhrbach for allowing us to use his current meter mooring for this experiment.
